1 Introduction

Retained customers in general create higher revenues than new customers do, and making a sell to a new customer can cost up to 5 times more depending on the business [2]. Therefore, many companies form the Customer Relationship Management (CRM) team with a focus on customer retention strategies. A crucial step is then to identify high risk customers who are intending to discontinue their usage of the services. This assessment is better known as *churn prediction*.

Our project aims to perform the churn prediction task based on investigation of customers's behavioural clusterings, and formulate the processes into a scalable pipeline which can be easily reused, updated and extended for many applications. In particular, we apply the pipeline to analyse pupil subscribers' data for Whizz Education (referred to as "Whizz"). Whizz provides online virtual tutorial service, Math-Whizz, which pupils can access by purchasing subscriptions. We have investigated whether behavioural-based data analytics can be used to help detect potential subscription cancellations.

The pipeline starts from representing pupils' behaviours by numerical data, also known as feature extraction. The structured features' data are fed into a mixture model that decodes features' distribution as a weighted combination of simple distributions. Since simple distribution is assumed to be generated by an unobserved state, we are interested in uncovering the states as well as their associated emitted feature distributions, also known as clusters. The mixture model is deemed to be effective if the identified clusters of pupils exhibit distinguishable proportions of churn, or churn rates. Assessing churn rate of the fitted mixture model results in a trained model that establishes a map between features to probability of churn. This enables the prediction of new coming pupils' churn probabilities by feeding their feature data into the trained model.

We show that clusters inferred from behavioural data are characterised by non-trivially different churn rate. Moreover, there is recognisable pattern observed in cluster sizes. This verifies the effectiveness of the mixture model approach in uncovering what level of churn risk the pupils are at. We further investigate how features impact churn probability and examine that the mixture model can result in very minimal overfitting issues in prediction practices. We also infer the temporal transitional probabilities of states by studying on the dynamics of behavioural changes.

The report is structured as follows. We start by elaborating the modelling framework and pipeline in section 2. Next in section 3 we describe the feature data preparation and pre-processing techniques used to adapt Whizz's data for better modelling performance. Then we explain the details of clustering analysis and model evaluation in section 4. Finally, we carry out prediction task and also assess overfitting issues, as detailed in section 5. We conclude the project with deliverables and future directions in section 6.

2 Modelling Customer Behaviours

Customers' behaviour evolves over time as they respond to business offering and adjust to their own demand. We would like to represent the various behaviour dynamics of a collection of customers by panel data, and employ the Markov chain model to describe these data. In addition, we use the mixture model to find Markov states, each of which defines a partition of the behaviours observable within a single time interval.

2.1 Representing Behaviours by Features

A feature is an individual measurable property of a behaviour being observed, and choosing informative features is crucial for effective clustering. For example, to measure how often the pupil uses Whizz online tutorial, we can define the time spent or number of visits within a month as the feature. For each customer, we define multiple features to capture his behaviours of various aspects within a time interval. Suppose we are interested in studying bahaviours of n customers in T discrete consecutive time periods, and define m features, then we denote the feature data as a sequence:

$$\{\mathbf{X}_1, \ \mathbf{X}_2, \ \dots, \ \mathbf{X}_t, \ \dots, \ \mathbf{X}_T\}, \tag{1}$$

in which the t-th element $\mathbf{X}_t = (x_{ij}^t) \in \mathbb{R}^{m \times n}$ is a matrix for all $t = 1, 2, \dots, T$. In addition, we denote the features of customer j at the t-th time interval by the j-th column of \mathbf{X}_t by $\mathbf{x}_{tj} = [x_{1j}^t \ x_{2j}^t \ \cdots \ x_{mj}^t]^\top$.

2.2 Customer Journeys and Markov Chain

Customer journeys reflect their feature dynamics over time, denoted as (1). One practical challenge of computing such sequence of matrices is to resolve the inconsistency present in journeys of different customers. The inconsistency refers to the problem that the time intervals for different customers being alive in the services are not aligned, so that their features are not comparable. Moreover, it is highly likely to have significant missing information within specific time intervals for customers who have not yet entered the service or have already churned. To resolve the inconsistency, we align and aggregate customers' features by customer month rather than calendar month. Doing so enables the effective modelling using Markov chain.

2.2.1 Customer Month

Splitting pupils' behaviours into monthly time periods makes most sense provided the business settings at Whizz. Pupils subscribe to access Whizz products on a 1-month contract, and make the choice to leave the service at the end of each subscription. If no action is taken, a renewal will be made by default.

Due to the inconsistency present in journeys of different customers, we align their features by switching the reference from calendar month to customer month. This is illustrated by an example in Figure 2.1. It provides much cleaner and more sensible data for modelling task.

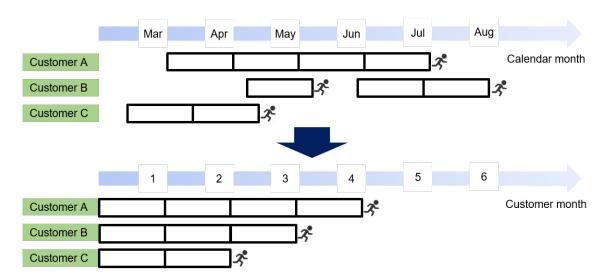

Figure 2.1: Change reference from calendar month to customer month. Customer A, B and C have very different journeys in the sense of subscription start and end dates. Each block represents customer's monthly features. Under calendar month reference, we have to choose studying months from March to August to cover all activities. This choice results in irregular temporal distribution of missing information for all 3 customers. After changing the reference to customer month, features are aligned by customer month and therefore comparable. Moreover, the missing information only occurs after the customer churns. It can also handle discontinuous subscriptions like the case of customer B.

2.2.2 Markov Chain - Dynamic Model for Behavioural Changes

We assume that customers with intentions to churn exhibit different behaviours than others do. Behaviours are different distributionally, and generated from a finite number of *states*. Then the discrete time behaviour of each customer results in a chain of states over time. This formulates into a discrete-time Markov chain with states transiting over time, where each state emits distinguishable behaviour distribution from others. An example is given in Figure 2.2.

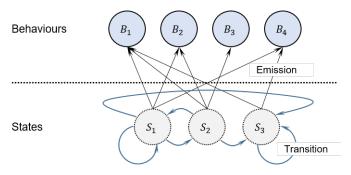

Figure 2.2: Behaviours emitted from Markov states. States S_1 , S_2 and S_3 generate differently distributed behaviours. For example, S_1 generates $\{B_1, B_2, B_4\}$ while S_3 produces $\{B_1, B_4\}$. Even if the two states can generate the same set of behaviours, the emission probabilities can be different, thus still resulting in different behaviour distributions. States transit between each other over time stochastically.

Consider the behavioural journey of customer j, which is represented by a se-

quence of feature data $\{\mathbf{x}_{tj}\}_{t=1}^T$. At time interval t, feature \mathbf{x}_{tj} is an instance from a distribution generated by a state. Let's denote the time sequence of generative states as $\{c_{tj}\}_{t=1}^T$. In a Markov chain setting the sequences are defined stochastically, with the next state being conditionally dependent on the present state, but not any further previous history. This is known as *Markov property*.

Markov State and Mixture Model

The goal is to assess the likelihood of customers canceling by examining their behaviors.

We model the behaviors of customers as the emission of Markov states, either hidden or observable. With this modelling assumption, we can also do temporal transitional analysis to gain insights of customers' dynamic behavioral change.

We can define states by some features.

We can also infer states from data through clustering task. To undertake the clustering task, we choose to use mixture model.

Schematic plot showing the relations between states and behaviors.

Schematic plot showing temporal transition of states.

Verify the first order markov property (stationarity assumption, the generative stochastic process is itself time invariant, and thus the parameters describing all probabilistic transitions are themselves constant)

2.3 Clustering Using Mixture Model

Generative process

$$\mathbb{P}(\mathbf{y}, \mathbf{c}, \boldsymbol{\theta}) = \prod_{k=1}^{K} G_0(\theta_k) \prod_{n=1}^{N} F(y_n | \theta_{c_n}) P(c_n)$$
(2)

- $\mathbf{y} = \{y_1, y_2, \cdots, y_N\}$, observations
- $\mathbf{c} = \{c_1, c_2, \cdots, c_N\}$, cluster assignments
- $\boldsymbol{\theta} = \{\theta_1, \theta_2, \cdots, \theta_K\}$, cluster parameters
- $G_0(\theta)$, a prior over the cluster parameters
- P(c), a prior over the mixing distribution
- $F(y_n|\theta_{c_n})$, a hypothetical distribution over the observations
- Assumptions: each observation is conditionally independent given its latent cluster assignments and the cluster parameters

Posterior probability of assignments

$$\mathbb{P}(\mathbf{c}|\mathbf{y}) = \frac{\mathbb{P}(\mathbf{y}|\mathbf{c})P(\mathbf{c})}{\sum_{\mathbf{c}}\mathbb{P}(\mathbf{y}|\mathbf{c})P(\mathbf{c})},\tag{3}$$

where

$$\mathbb{P}(\mathbf{y}|\mathbf{c}) = \int_{\theta} \left[\prod_{n=1}^{N} F(y_n | \theta_{c_n}) \prod_{k=1}^{K} G_0(\theta_k) \right] d\theta$$
 (4)

BNP clustering assume that there is an infinite number of latent clusters (namely $K \to +\infty$), but that a finite number of them is used to generate the observed data. There are an infinite number of clusters, though a finite data set only exhibits a finite number of active clusters.

2.4 Modelling Pipeline

Feature extraction

Features distributional modelling

Fitting mixture model

Analytic (churn rate calculation, clusters interpretation)

3 Data Description and Pre-processing

3.1 Whizz Database

Imbalanced data - the reason we don't mak them balanced is because we do not want to twist numerical value of churn rate. For example, if we balance the data set perfectly, then the population churn rate will become 50%. After we do the clustering task, it is not straightforward to transform back the cluster churn rate for the balanced data set to that for the original imbalanced data set.

3.2 Feature Extraction

A table showing the definition of features.

3.3 Data Transformation

We denote the feature data by a matrix $\mathbf{X} = (x_{ij}) \in \mathbb{R}^{m \times n}$, which describes n observed values for each of the m features. In addition, we denote the i-th row of \mathbf{X} by $\mathbf{x}_{i,R} = [x_{i1} \ x_{i2} \ \cdots \ x_{in}]$, and the j-th column by $\mathbf{x}_j = [x_{1j} \ x_{2j} \ \cdots \ x_{mj}]^{\top}$.

In general, learning algorithms benefit from standardisation of the data set. We have employed 3 transformations in sequence to make our data more suitable for mixture model learning task. The transformations are performed for each feature separately, resulting in different sets of transformation parameters for different features. To be specific, for *i*-th feature we describe the transformations as following.

• Linear transformation

The linear transformation is applied either to ensure all data to be positive

for eligibility of applying the following power transformation, or to adapt to distributional modelling choice. It has the format:

$$\mathbf{x}_{i,\mathrm{R}}' = a_i \mathbf{1} + b_i \mathbf{x}_{i,\mathrm{R}},\tag{5}$$

where a_i and b_i are constants and $\mathbf{1} \in \mathbb{R}^{1 \times n}$ is the row vector of all ones.

• Box-Cox power transformation

The Box-Cox power transformation is used to modify the distributional shape of a set of data to be more normally distributed so that tests and confidence limits that require normality can be appropriately used. It has the format:

$$x'_{ij} = \begin{cases} \frac{x_{ij}^{\lambda_i} - 1}{\lambda_i} & \text{if } \lambda_i \neq 0, \\ \ln x_{ij} & \text{if } \lambda_i = 0, \end{cases}$$
 (6)

for j = 1, 2, ..., m. In Box-Cox transformation, λ_i is estimated by maximizing the likelihood function [reference].

Standardisation

We standardise data for different features by scaling them into the same range to ensure the robustness to very small standard deviations of features. We choose to scale all features into range [1, 100]. If we denote the maximum and minimum values of observed feature i as x_i^{\max} and x_i^{\min} respectively, then the standardisation is a linear transformation such that,

$$\mathbf{x}'_{i,R} = \mathbf{1} + \frac{100 - 1}{x_i^{\text{max}} - x_i^{\text{min}}} (\mathbf{x}_{i,R} - x_i^{\text{min}} \mathbf{1}).$$
 (7)
